Surgical anatomy of the femoral nerve in formalin prefixed cadavers in an adult Kenya population

Dr. Momanyi Alex, Dr. Barry Ayumba and Mohamed GY El-badawi

DOI: https://doi.org/10.22271/ortho.2022.v8.i1h.3075

Abstract

Background: Ethnic variations involving femoral nerve have been described in literature. This nerve is the largest branch of the lumbar plexus. It innervates the hip flexors, knee extensors, and sensory function to medial and anterior aspects of the thigh. Risks of insults to nerve can be non-iatrogenic (trauma), and iatrogenic (approaches to the acetabulum, pelvis and proximal femur). The study aimed at providing precise description of variant anatomy of nerve, hence will help surgeons avoid iatrogenic insults.

Methods: An anatomic descriptive cross-sectional study design involving fifty six (56), formalin prefixed adult cadaveric specimens. The length of the femoral nerve in relation to the inguinal ligament and its bony attachments, and the patterns of distribution of main branches in the regions were defined.

Results: Males- 35 (Left=17, Right=18); Females- 21 (Left=7, Right=14). Femoral nerve location: 53.02 mm (SD 14.59) from the ipsilateral anterior superior iliac spine (ASIS). Nerve trunk in relation to inguinal ligament measured: 47.85mm (SD 13.719) from the psoas muscle proximally and branched 29.32 mm (SD 14.239) distally. Innervations and branches: quadriceps in all specimens (Posterior); Sartorius muscles (Anterior), with noted variability in individual muscles. Branching pattern variations: 6 limbs (10.71%) at ligament level, 2(3.57%) limbs more proximal, while one nerve was split by a slip from the psoas muscle and then united 25.88mm proximal to ligament. The variations in sex were not statistically significant (p > 0.05).

Conclusion: The anatomical course, length and branches of the femoral nerve in relation to inguinal ligament concur to great extent with described anatomic studies with some noted variability. Surgeons should be aware of the anatomic variations of femoral nerve and be cautious when operating in the zones traversed by the nerve.

Keywords: Femoral neuropathy, iatrogenic femoral nerve injury, acetabular/pelvic/ proximal femur surgery, femoral nerve orthoplasty

1. Introduction

The femoral nerve is the largest branch of the lumbar plexus arising from the posterior division of the ventral rami of L2, L3 and L4 nerve roots [occasionally receiving L1 and L5 spinal nerve roots]. Its trunk emerges on the anterolateral aspect of the psoas major muscle approximately 4cm proximal to the inguinal ligament [1][4]. It traverses beneath the inguinal ligament to emerge within the femoral triangle lying lateral to the femoral sheath. The nerve emerges in a groove between the iliacus and psoas muscles at the midpoint of the inguinal ligament where its course is directly anterior to the capsule of the hip joint separated by the iliopsoas tendon [5]. It then divides 2-4cm [1-1.5inches] below the mid-point of the inguinal ligament into the anterior and posterior branches. The anterior branch has motor [pectineus and sartorius muscles] and sensory [intermediate and medial cutaneous femoral nerves] branches. The posterior branch has motor [quadriceps femoris] and sensory [saphenous nerve] branches [6].

The femoral nerve function plays an important ambulatory role primarily in the stance phase of gait [7]. The documented ethnic and demographic variations in course and branching pattern [8] and its intimate relationship with the pelvis, hip joint and proximal femur places it at risk of injury through dislocations, fractures, direct blows or surgery. Femoral neuropathy results in ipsilateral hip flexion and knee extension deficits and hypoesthesia impairment on the anteromedial aspect of the thigh [9] and patella areflexia.
Injury is associated with high patient morbidity with impairment in basic daily functions including walking, climbing up and down stairs. There has been a gradual increase in cases of femoral neuropathy following hip arthroplasty [9]. The increasing number of non-iatrogenic and iatrogenic femoral nerve insults, the documented ethnic variations, and the unknown course of the femoral nerve among the Kenyan population demonstrate the need for an anatomic description of the nerve among our population.

Findings could be applied in validating previously described femoral nerve anatomy applicable in preoperative and intraoperative planning. Findings from this study will provide a precise anatomical guide to orthopaedic and non-orthopaedic surgeons in various pelvic and pelvic surgeries [10]. Morphometric findings from this study could act as a foundation for subsequent related studies. Precise anatomical knowledge of the femoral nerve will minimise direct transection, electrocautery or suture placement associated femoral nerve insults.

Methods
2.1 Study site
The study was conducted at the Human Anatomy Laboratory, Moi University School of Medicine.

2.2 Study design
The study was an anatomical descriptive cross-sectional design.

2.3 Study population
This included sequentially selected adult Kenyan formalin prefixed cadaveric pelvic and lower limb specimens. Majority of the limbs available were disarticulated along the Hemipelvectomy planes. This plane extends along the pubic symphysis and the ipsilateral sacroiliac joint with preservation of the ipsilateral pelvic bones. This preserved the bony attachments of the inguinal ligament as well as the distal portions of the psoas major and iliacus muscles. Thus, the proximal portion of the femoral nerve as it emerges at the anterolateral distal portion of the psoas major was followed to the level of the inguinal ligament. Sex of the cadavers was recorded in the data collection sheet.

2.4 Eligibility Criteria
2.4.1 Inclusion criteria
All adult pelvic and lower limb cadavers without gross evidence of fracture, pathology or prior surgery were included.

2.4.2 Exclusion criteria
Deformed or mutilated cadavers were excluded from the study.

2.5 Sampling and Sample size determination
The maximum number of affixed unilateral pelvic and lower limb cadaveric specimens attainable at the Moi University Human Anatomy Laboratory meeting the inclusion criteria totalled 56 specimens.

2.6 Data Collecting Materials/Tools and Methods/Techniques
2.6.1 Data Collecting Materials/Tools
The cadavers were dissected, and the parameters were measured using a Vernier calliper accurate to 0.01mm. Data was captured in structured data collection forms. The innervations patterns of the main branches [anterior and posterior] were also photographed using a digital camera [Sony® DSC-W180 10.1 megapixels].

2.6.2 Data Collection Technique/Method
Dissections were done according to the techniques described by The Cunningham’s Manual of Practical Anatomy 16th Edition [11]. Muscular branches of the femoral nerve were identified, and their course described by dissection of the anterior compartment of the thigh. The distance of the femoral nerve at the level of the inguinal ligament from the anterior superior iliac spine was measured and labelled as AFN. Similarly, the distance of the femoral nerve at the level of the inguinal ligament from the pubic symphysis was measured and labelled as PFN. The length of the femoral nerve proximal to the inguinal ligament as it emerged on the anterolateral aspect of the psoas major was measured and labelled as FN1. The length of the femoral nerve just distal to the inguinal ligament to its point of division into the main branches [anterior and posterior] was measured within the femoral triangle and labelled as FN2. The points of innervations of the muscular branches was also recorded within the femoral triangle and labelled in relation to the muscle to which it innervated.

The measurements obtained were subjected to statistical analysis to determine any statistically significant differences in nerve distribution between both sexes.

3.5 Observed anatomical branching pattern variations.
Any anatomical variation in the femoral nerve was also noted for each record. Majority, 47[83.93%] [71.67-92.38], of the cadaveric limbs had no observed anatomical variations observed. However, 6 cadaveric specimens, [10.71%] [4.03-21.88], demonstrated the nerve branching at the level of the inguinal ligament. A further 2[3.57%] [0.44-12.31] had a more proximal branching above the level of the inguinal ligament [Figure 9]. One cadaveric limb had the femoral nerve branching 30.44mm while the other 27.39mm proximal to the level of the inguinal ligament.
One studied specimen had a more variant anatomy with a slip from the psoas muscle dividing the nerve trunk into two divisions that were uniting 25.88mm proximal to the inguinal ligament [Figure 10].

3.6 Gender-stratified Sub analysis

Stratified analysis for each of the sex of the limbs was conducted to ascertain existence of any gender differences.

The comparative sub analysis of individual measurements demonstrated variability in lengths between genders but the \( p \)-values >0.05 demonstrated no statistical significance in variance. This demonstrates no significant gender differences as shown in literature.

**Discussion**

Descriptions of iatrogenic insults and position of the femoral nerve in relation to the proximal femur have been documented [12, 13]. Some studies have demonstrated position of the femoral nerve with various subtypes of femur neck fractures and possibility of iatrogenic insults [14]. Cadaveric studies have further demonstrated variant course and branching of the femoral nerve even with reference to the individual nerve roots precedent to and after the formation of the nerve [4, 15-17]. This variability should be considered in individuals presenting with idiopathic atraumatic/traumatic motor or sensory deficits along the femoral nerve innervation dermo-myotome path. Femoral nerve blocks are also useful in providing anaesthesia and postoperative analgesia for non-hip fracture surgery and extracapsular neck of femur fractures [14].

### 4.1 Length of the femoral Nerve and its Muscular branches

The mean length of the nerve proximal to the inguinal ligament but distal to anterolateral border of the psoas muscle was 47.85mm [SD 13.719], concurs with documented findings [1, 2]. However, there is paucity of studies with reference to any ethnic/racial variability and with regard to the muscle bulk of the psoas muscle or in relation to actual length of the individual nerve roots. This therefore demonstrates that the nerve underlies the fascia iliaca for around 5cm proximal to the inguinal ligament which should be considered in patients presenting with hip/knee arthralgia as a consequence of iliacus hemATOMA or abscesses [16-21].

The mean length of the femoral nerve distal to the inguinal ligament to the point of branching into anterior and posterior branches was 29.32 mm [SD 14.239]. This was slightly higher than that described on average by Gustafson et al., [2009] [22] at 15.0 mm which would propose a slightly more distal branching point in our population. Vloka et al., 1999 [23] in a New York based cadaveric study involving 9 specimens described the nerve branching within 2.5cm distal to the inguinal ligament and its importance in appropriate estimation for femoral nerve regional anesthesia block necessary for orthopedic procedures. This figure still fell slightly short of our mean finding suggesting a longer nerve length distal to the inguinal ligament in Kenyan population.

The femoral nerve mean length was 53.02 mm [SD 14.59] from the ipsilateral anterior superior iliac spine at the level of the inguinal ligament. This finding was lower than that described in a multi-ethnic retrospective MRI study based in Chicago by Watson, Bohnenkamp, El-Bitar, Moretti, and Domb, [2014] [8], which averaged at 28.67mm. The findings in our study were close to the vectors measured among African Americans and Hispanics described in the study. This might demonstrate that the femoral nerve distance from the ASIS among Caucasians and Asians as ascribed in the study might be smaller compared to that in Kenyan population.

At the level of the inguinal ligament the mean length of nerve was 72.87mm [SD 19.75] from the midline of the symphysis pubis. Overall the described cumulatively averaged mediolateral distance from the ASIS to the pubic symphysis corresponded with literature findings [21] with the nerve being at the midpoint of the inguinal ligament. This concurs with the finding in the Kenyan study that the nerve was slightly lateral to the mid – inguinal point. The above findings suggest that in Kenyan population the femoral nerve lies at the midpoint of the inguinal ligament lying averagely 53mm from the ASIS and around 73mm from the midpoint of the pubic symphysis. This therefore approximates the position of the nerve to avoid iatrogenic insults while doing certain approaches to the pelvis and proximal femur including the ilioinguinal, Stoppa, Iliofermoral and Smith Patterson approaches with reference to the commonly used intraoperative anatomic bony landmarks [12].

### 4.2 Branching patterns

Similar to two Chinese cadaveric studies by Boo-Chai, [1984] [24] and Yu et al., [2010] [23], the majority of the specimens demonstrated a single branch coursing deep to the Sartorius muscle proximally with some specimens having 2 to 3 subbranches to the muscle. However, 21.43%, of our specimens had 2-3 twigs arising directly from the anterior branch and coursing deep to the muscle. This finding further augments usability of the Sartorius muscle for muscle compartment transfer in reconstructive arthroplasty.

Innervation to the rectus femoris from our study was from the posterior branch which was mostly through a single branch deep to the muscle, 27[48.21%] [CI 34.66-61.97], or along the medial border, 26[46.43%] [CI 33.99-60.26]. This concurred with a Canadian cadaveric study by Yang and Morris, [1999] [26] in which the rectus was innervated by a single muscular branch from the posterior division deep/posterior to the muscle or along the medial border. However, it was not noted to split into 2 branches before entering the muscle as described in the study. Sung et al., [2003] [27] in a Korean cadaveric study demonstrated findings which concurred with Kenyan study with the nerve running along the medial border but described 2 subbranches with the superior subbranch.

~ 586 ~
running deep with the inferior entering the muscle along the
medial border. Therefore, our Kenyan study findings concur
with those described in other studies showing no noted
interracial/ethnic variability with reference to innervation of
the rectus femoris from the femoral nerve.

Consideration was made for the innervation of the remaining
three vasti muscle of the quadriceps femoris group. The
innervation pattern for the Vastus lateralis muscle, almost all,
54 [96.43%] [CI 87.69-99.56], revealed an innervation of a
single branch along the medial border of the muscle. There
were only two exceptions to this pattern, one with four
branches to the medial border of the muscle and another with
two branches to the medial border each representing 1.79%
[CI 0.05-9.55]. Sung et al., [2003] [27] in a Korean cadaveric
study demonstrated similar findings but majority of the
specimens had 2 subbranches along the medial border. This
would suggest no difference in variability in the innervation
pattern of the vastus lateralis between Koreans and Kenyan
population other than presence of subbranches before
perforating the medial aspect of the muscle.

However, unlike the Korean study by Sung et al., [2003] [27],
innervation of the Vastus Intermedius in Kenyan study was
along the medial border, 44[78.57%] [CI 65.56-88.41], with
only a few having superficial nerves perforating the muscle
12[21.43%] [CI 11.59-34.44]. Both studies however demonstrate
a single nerve to the intermedius muscle. Thiranagama, [1990] in a Sri Lankan cadaveric study made mention of the vastus intermedius receiving a nerve slip from
later branch of the nerve to the vastus medialis but this was
not evident in any of the Kenyan specimens dissected. Our
study findings therefore concur with the general described
consensus on innervation of the femoral nerve. There was
however paucity of cadaveric studies further describing the
innervation pattern of the vastus intermedius muscle.

Similar to an Indian cadaveric study by Rajput, Rajani, and
Vaniya, [2017] [28] and a south African cadaveric study [30],
the vastus medialis was solely innervated from the posterior
branch of the femoral nerve, but no relation to the subsartorial
canal was mentioned. It was further described that the nerve
further subdivided before entering the substance of the
muscle. A southern Asian [Sri Lankan] study by Thiranagama, [1990] [28] involving 30 cadaveric limbs with a
higher male ratio made mention of the nerve to vastus medialis within the adductor canal as found in the Kenyan
study but describes this branch as the thicker medial branch
from the posterior division. Unlike the Kenyan study, there
was mention of an additional slender lateral branch which
arose directly from the posterior division of the femoral nerve
and made no entry into the adductor canal and further
innervated the vastus intermedius.

4.3 Observed anatomical branching pattern variations.
Similar to a French cadaveric study by Galtier et al., [1995] [31] and a Korean study by Sung et al., [2003] [27] no
differences were observed between right and left limbs as
described in literature. No gender differences were observed
as has been described in literature [15, 27, 31].

In most of the specimen, no anatomical variation was observed
47[83.93%] [71.67-92.38]. However, 6 cadaveric specimens
[10.71%] [4.03-21.88] demonstrated the nerve branching at the level of the inguinal ligament. A variation
described in literature by Das and Vasudeva, 2007 [32] in an
Indian cadaveric case report, was observed in 2[3.57%] [0.44-
12.31] limbs having a more proximal branching above the
level of the inguinal ligament. One cadaveric limb had the
femoral nerve branching 30.44mm while the other 27.39mm
proximal to the level of the inguinal ligament. This was
almost similar to the measurement described at 32mm. Astik
and Dave, [2011] demonstrated a similar variation but the
measurements were larger at 40mm and 38 mm [15].

One studied specimen had a more variant anatomy with a slip
from the psoas muscle dividing the nerve trunk into two
divisions that were uniting 25.88mm proximal to the inguinal
ligament. This variation has been described in an Asian
cadaveric study by Astik and Dave, [2011] [16] in which the
nerve trunk united 40 and 45mm proximal to the inguinal
ligament. Variant slips of the iliopectos major muscles split the
femoral nerve into 2 or 3 slips in 35.3% [16], 7% [13] and 2.2%
[33]. Jelev et al., [2005] reported an accessory iliopectos muscle
which split the left femoral nerve in a female cadaver [34].

Variant muscular slip of psoas major or accessory slips from
iliacus which cause tension of the femoral nerve should be
suspected in patients with referred pain to the hip and knee
joints [17]. This variation is an important differential in
persistent knee and hip arthralgia in orthopaedic patients and
can be accentuated by hyperextension or external hip rotation.

4.4 Gender stratified sub analysis
A sub analysis was conducted to determine any existing
differences between male and female specimen. On
comparison of all the measurements between males and
females, it was noted that the confidence intervals overlap, an
indication that there is no statistically significant differences
between the two genders as described in literature [15, 27, 31].

5. Conclusion
The course, length, and distribution of the femoral nerve in
the Kenyan population concur to some extent with described
anatomic studies with some noted variability. The zone 53.02
mm [SD 14.59] from the ASIS or 72.87mm [SD 19.75] from
the pubic symphysis at the level of the inguinal ligament
should be approached with caution when making incisions to
the pelvis/proximal femur as this would place the femoral
nerve at risk of iatrogenic insult.

grants or sponsorship were sought/received.
6. Acknowledgements
Foremost, I would like to express my sincere gratitude to colleagues for the continuous support of this research project, for their patience, motivation, enthusiasm, and immense knowledge.

6.1 Data availability Statements: The data that support the findings of this study are available from the corresponding author, [A.M.], upon reasonable request.

7. Ethical considerations
Prior to commencement of the study, ethical approval was sought from the Department of Human anatomy and the Institution Research and Ethics Committee (IREC) Moi University. The Anatomy Act Chapter 243-9 (Revised Edition of 2012) of The Laws of Kenya (48) was strictly adhered to. This act states and entitles a person registered as a student in an approved school of anatomy to examine and conduct anatomical research on human cadavers as long as the requirements stipulated in the act are strictly adhered to. Data confidentiality was strictly maintained and this included use of passwords in the database.

- IREC Moi University Approval Number: 0003353
- Reference number: IREC/2019/143
